## **Abstract**

The use of Silicon Carbide Field Effect Transistor (SiC-FET) sensors in cyclic operation is a proven way to quantify different gases. Standard workflow involves extracting shape defining features such as average and slope of the sensor signal. This work's main goal is to verify if frequency modulation can be used to simultaneously quantify Nitric Oxide (NO), Nitrogen Dioxide (NO<sub>2</sub>) and Ammonia (NH<sub>3</sub>). Linear models were chosen, namely: Ordinary Least Squares (OLS), Principal Components Regression (PCR), Partial Least Squares Regression (PLSR) and Ridge regression. Results indicate that these models fail to predict concentrations completely for every gas. Analysis indicates that the features are not linear in terms of concentrations. This work is concluded by recommending a few other alternatives before discarding frequency cycling completely: non-parametric models of regression and different frequency regime, namely the use of triangular waves in future experiments.

# Acknowledgments

Foremost, I would like to extend my deepest gratitude to my internal supervisor, Annika Tillander, for her insightful comments, feedback, and continuous support. I cannot stress enough her patience, availability, compassion, and constructive criticism enough.

I am also extremely grateful to my external supervisor, Mike Andersson, who offered me this project in the first place and whose support was indispensable throughout this thesis. Our formal and casual conversations, lab visits, and meetings surely made an already exciting topic even more enjoyable.

Moreover, I am deeply indebted to have José M. Peña as my examiner. I feel he greatly enhanced my work through his thorough review, appreciation, meaningful comments and valuable suggestions.

Special thanks to Lida Khajavizadeh, who was co-responsible for lab experiments and data collection.

I'd like to acknowledge the assistance of my colleagues Erik Rosendal and Mudith Chathuranga Silva, who helped shape this report via proof-reading and excellent suggestions. For that, I thank you.

Additionally, I would like to thank my friends Agustín Valencia, Bayu Brahmantio, José Mendez, and Ismail Khalil for their continuous support and meaningful discussions during our thesis work.

Finally, I would like to dedicate this work to my beloved parents, Katia and Marcio. Unfortunately, there is not enough space in this thesis to even begin describing how grateful I am to them.

To all of you, I offer my sincere appreciation, respect, and gratitude.

Sincerely,

Marcos Freitas Mourão dos Santos

# 1 Introduction

## 1.1 Motivation

Nitric Oxide (NO) and Nitrogen Dioxide (NO<sub>2</sub>), commonly referred together as NO<sub>x</sub>, are hazardous gases to the environment and to humans. Its main sources are combustion processes in transportation, and industrial processes such as (but not limited to) auto mobiles, trucks, boats, industrial boilers, turbines, etc. (USEPA 2019).

NO<sub>x</sub> exposure to humans can cause respiratory illnesses such bronchitis, emphysema and can worsen heart disease (Boningari and Smirniotis 2016). Environmentally, NO<sub>x</sub> are deemed precursors of adverse phenomena such as smog, acid rain, and the depletion of ozone (O<sub>3</sub>) (Alberto Bernabeo, Webster, and Onofri n.d.). It is of high interest, therefore, to reduce NO<sub>x</sub> emissions.

One well studied and successful method of reducing emissions is Selective Catalytic Reduction (SCR), which consists in the reduction of NO<sub>x</sub> by ammonia (NH<sub>3</sub>) into nitrogen gas (N<sub>2</sub>) and water (H<sub>2</sub>O) (Forzatti 2001), both harmless components. The process is based in the following reactions (Forzatti 2001):

- 4 NH<sub>3</sub> + 4 NO + O<sub>2</sub> → 4 N<sub>2</sub> + 6 H<sub>2</sub>O
- 2 NH<sub>3</sub> + NO + NO<sub>2</sub> → 2 N<sub>2</sub> + 3 H<sub>2</sub>O
- 8 NH<sub>3</sub> + 6 NO<sub>2</sub> → 7 N<sub>2</sub> + 12 H<sub>2</sub>O

One key element in these reactions, however, is the amount of ammonia dosed into the SCR systems. Ammonia itself is hazardous to humans, causing skin and respiratory irritation, among other illnesses (ASTDR 2004). More importantly, ammonia is one of the main sources of nitrogen pollution and it has direct negative impact on biodiversity via nitrogen deposition in

soil and water (Guthrie, Giles, Dunkerley, Tabaqchali, Harshfield, Ioppolo, and Manville 2018). Hence it is also desired to keep ammonia emissions to a minimum. Too much ammonia in the SCR catalyst will guarantee NO<sub>x</sub> reduction at the expense of undesired ammonia emissions. Concurrently, too little ammonia will impede SCR to occur properly, beating the purpose of the catalyst and as a consequence, undesired NO<sub>x</sub> emissions.

To monitor gasses concentrations, chemical sensors are deployed, one of which is the Silicon Carbide Field Effect Transistor (SiC-FET). The identification and quantification of gasses is normally achieved through multiple sensor in so called sensor arrays. Ideally each sensor in the array needs to have different responses to different compounds (Bastuck 2019). The deployment of multiple sensors, on the other hand, proves itself cumbersome due to the increased chances of failure, and decalibration of the system should one or multiple sensors be replaced (Bastuck 2019).

One solution to this problem is the cycled operation of one single sensor, referred as virtual multi-sensor (Bastuck 2019). By cycling the working point parameters of the sensor, different substances react differently in the sensor surface, which in turn produces different responses. Temperature Cycled Operation (TCO), Gate Bias Cycled Operation (GBCO), and the combination of the two have been proven to increase selectivity of SiC-FET sensors (Bastuck 2019).

TCO, in contrast with a constant temperature evaluation, produces unique transient sensor responses, i.e. each gas mixture yields a slightly different sensor output. This unique gas signature increases selectivity (Bur, Bastuck, Lloyd Spetz, Andersson, and Schütze 2014). Additionally, the high temperatures reached in these cycles help in the cleansing of the sensor surface, preparing it for the new mixtures to come.

Frequency modulation tries to achieve the same goal: avoid steady state responses in exchange of unique signatures that could help identify/quantify the gasses at hand. It consists on operating the sensor in Alternating Current (AC). One then can regulate the frequency of this operation and create cycles of different frequencies, similar to what is done in TCO. This is equivalent to GBCO, but with more frequency changes and achieving overall higher frequencies.

The main question is: given these set of   sensor responses, how one can quantify the gasses that produced them? Multivariate regression techniques have been shown to be successful: Partial Least Squares Regression (PLSR) has been used in chemometrics extensively and it has been proven to be good at this task (Bastuck 2019) (Wold, Sjöström, and Eriksson 2001). Other multivariate regression methods, naturally, can also be used.

## 1.2 Aim

The aim of this thesis is to investigate if frequency modulation can be used to simultaneously quantify the concentrations of NO<sub>x</sub> and Ammonia in a particular gas mixture.

### 1.3 Research questions

1. Can frequency modulation be used to simultaneously quantify NO<sub>x</sub> and Ammonia concentrations?
2. Which method yields best predictions of gas concentrations.

## 2 Data

### 2.1 Data acquisition

The data was acquired at the Sensor and Actuator Systems (SAS) laboratory at Linköping University. The experiment — as shown on Figure 2.1 — consisted of exposing different gas combinations to two SiC-FET sensors under a particular frequency cycle and recording its response, measured in miliamperes (mA). This is then used to extract secondary features, namely average and slope values from certain regions of the frequency cycle.

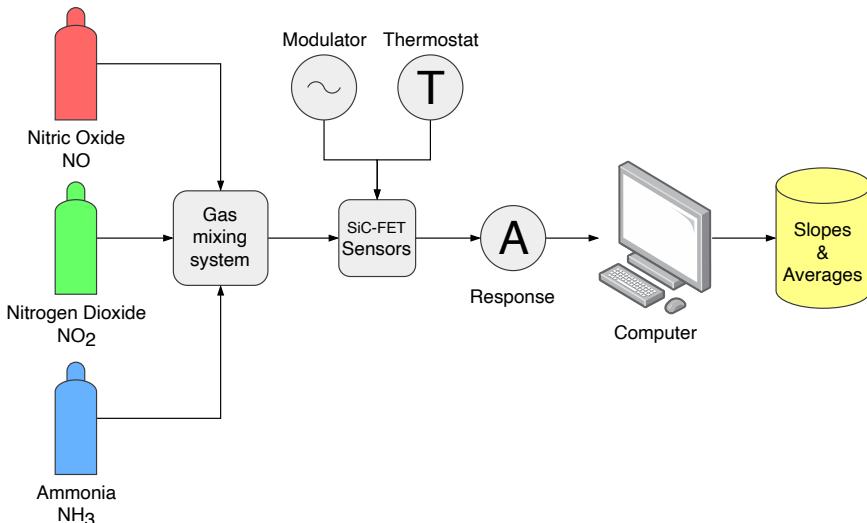

Figure 2.1: Schema of the data acquisition process.

In more detail, NO, NO<sub>2</sub> and NH<sub>3</sub> had five possible concentration values each: 5, 10, 20, 40, and 80 parts per million (ppm). The experiment was designed to encompass all possible combinations of these gases, amounting to 125 different gas mixtures. Each feature was sub-

mitted to the same frequency cycle four times. The cycle consists of 16 unique frequencies: 0.05, 0.1, 0.25, 0.5, 1, 2, 5, 10, 25, 50, 100, 200, 500, 1000, 2500 and 5000 Hertz (Hz). A typical raw sensor response for frequency modulation experiments is shown on Figure 2.2.

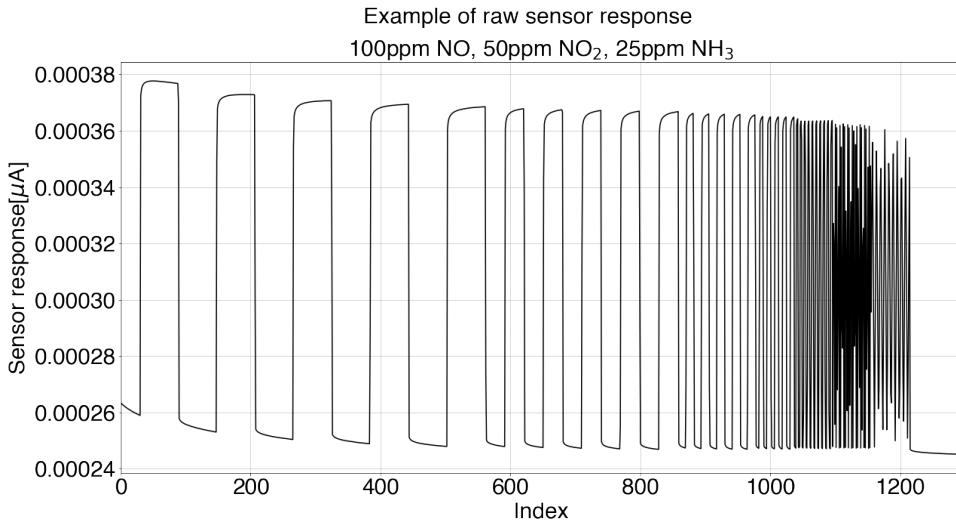

Figure 2.2: An example of raw sensor response

Throughout one cycle, several slope and average features were extracted. The sample rate for feature extraction was set at 4 Hz, i.e. in a cycle of 60 seconds, a total of  $60\text{s} \times 4\frac{1}{\text{s}} = 240$  pairs of slopes and averages are recorded, which totals to 480 features per cycle. In other words, during one experiment – 4 cycles of 60 seconds – a total of  $480 \times 4 = 1920$  features are extracted.

One way to visualize this process is shown in Figures 2.3. Note that the y-axis is in log-scale due to the different orders of magnitude of frequencies. Moreover, Figure 2.4 gives more insight into feature measurement and Table 2.1 summarizes the data acquisition details.

Table 2.1: Data acquisition details

Parameter	Value
Factors (gases)	3
Levels (concentrations)	5
Frequencies	16
Features per cycle	480
Number of cycles	4
Data points per mixture	1920
Number of mixtures	125
Features per experiment	240.000
Number of experiments	3
Total features	720.000

For specific timestamps and measurement durations, the reader is referred to Appendix A.

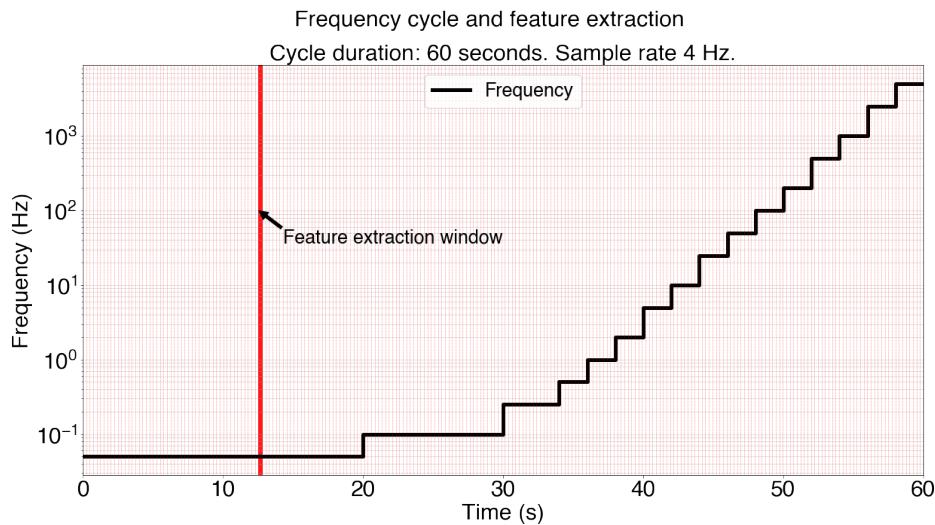

Figure 2.3: Feature measurements times per cycle. The width of the red line indicates the duration of one of the feature measurement windows as an example.

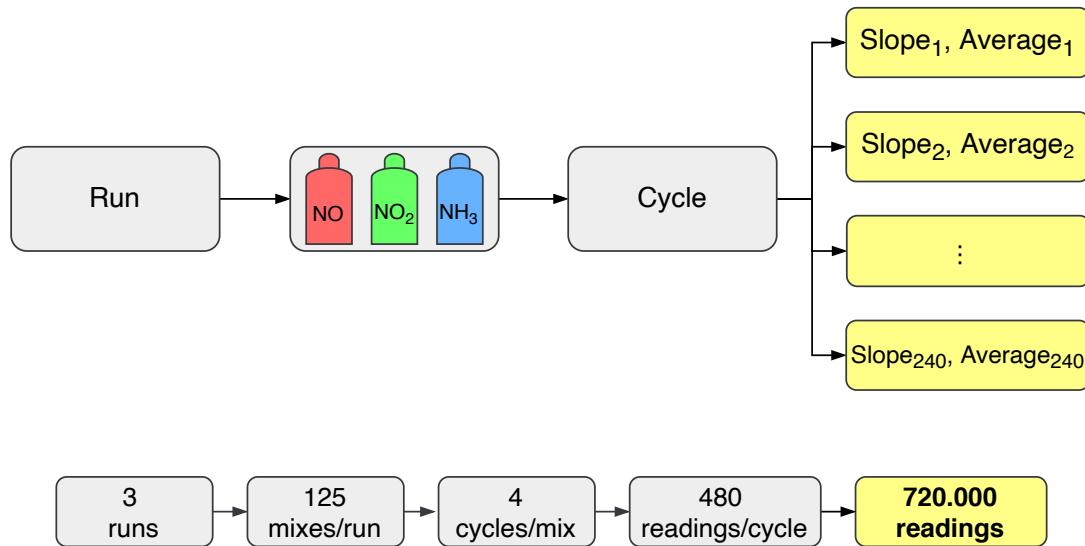

Figure 2.4: A visualization of the feature measurement process.

## 2.2 Raw data

The experiments were run between 26th and 29th March, 2021. The experiment data was exported as an excel file containing twelve columns, as specified in Table 2.2

Table 2.2: Raw data column details

Name	Description	Unit
Exposure nr	A particular mix of NO, NO <sub>2</sub> and NH <sub>3</sub> . Ranges from 1 to 375	-
Cycle nr	The cycle number. Ranges from 1 to 4.	-
Sample nr	Extracted feature index. Ranges from 1 to 240	-
NO	Nitric Oxide concentration	ppm
NO <sub>2</sub>	Nitrogen Dioxide concentration	ppm

## 2.3 Pre-processing

The features (slopes and averages) from the same target (a particular exposure) in the raw data file in Table 2.3 are spread across multiple rows, which is not suitable for analysis. Opposed to TCO, the experiments were conducted at constant temperature and therefore the temperature column is discarded. The data was, subsequently, modified to have the desired format: each row containing the predictors for one particular combination of gases. Additionally, the data from each sensor was split into two datasets.

The naming convention for the features is shown in Figure 2.5. First, the frequency in which the measurement was taken followed by the sensor number. After that, the feature name itself is followed by its index, i.e. where in the frequency cycle the measurement was made. This convention allows for easy identification of key information of the cycle and measurement.

The pre-processing results in the format shown in Figure 2.6. Recalling that there are 125 possible mixtures of gases, it is important to note that there are repeated exposures in the data set and those are treated as individual observations. Since each unique gas mixture was exposed 4 times during a cycle, and the experiment was repeated 3 times, this yields a total of  $4 \times 3 \times 125 = 1500$  exposures. A snippet of the final data set is shown in Table 2.4.

In efforts to further analyze the data, the previous 1500 observations are averaged by unique mixtures, i.e. for each mixture, the features are averaged from its twelve exposures, yielding 125 observations. Figure 2.7 clarifies this further. Table 2.5 contains the averaged slopes and averages per unique mixture. Analysis will be run in this data set separately as means of comparison. The lower number of data points here gives opportunity to visualize the data in a plot; this is done in Figure 2.8.

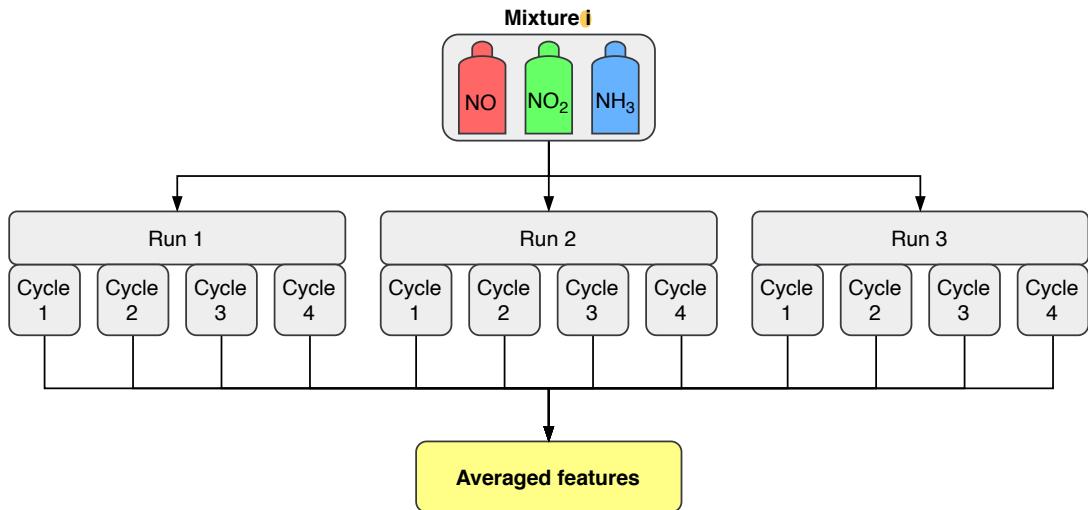

Figure 2.7: A visualization of the feature averaging process.

Table 2.5: Sample of averaged features throughout all exposures data.

In each plot, each line represents a unique gas mixture.

## 3 Theory

The quantification of gases based on the sensor response can be viewed as a multivariate multiple regression problem where the predictors, i.e. features derived from the sensor signal, are used to predict multiple responses, i.e. the concentrations of pertinent gases. This chapter exposes the theory behind some of these models.

The models here listed were chosen as a natural progression from a statisticians point of view: starting with simple models and progressively increasing complexity as insights from the data and the problem are gathered.

### 3.1 Notation

In favor of consistency and clarity, the notation used throughout this work is presented here. Bold capital letters, e.g.  $\mathbf{A}$ , are matrices while bold lower case letters are row vectors, e.g.  $\mathbf{a}$ . Scalars, on the other hand, are denoted as standard lower case letters, e.g.  $a_{i1}$ . Transposes and inverses are denoted, respectively with  $\cdot^\top$  and  $\cdot^{-1}$ . An example is shown below.

$$\mathbf{A} = [\mathbf{a}_1, \mathbf{a}_2, \dots, \mathbf{a}_n]^\top$$

$$\mathbf{A} = \begin{bmatrix} \mathbf{a}_1 \\ \mathbf{a}_2 \\ \vdots \\ \mathbf{a}_n \end{bmatrix} = \begin{bmatrix} a_{11} & a_{12} & \dots & a_{1p} \\ a_{21} & a_{22} & \dots & a_{2p} \\ \vdots & \vdots & \ddots & \vdots \\ a_{n1} & a_{n2} & \dots & a_{np} \end{bmatrix}$$

## 3.2 Ordinary Least Squares Regression

A simple, first approach would be to tackle the problem with the Ordinary Least Squares (OLS) regression model. As Friedman, Hastie, Tibshirani, et al. 2001 explains, each output  $\mathbf{Y} = [y_1, y_2, \dots, y_K]^T$  has its own linear model. Now, given a set of  $n$  observations  $\mathbf{X} = [\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_n]^T$  and each observation having  $p$  features, e.g.  $\mathbf{x}_i = [x_{i1}, x_{i2}, \dots, x_{ip}]$ ,  $i = 1, 2, \dots, n$ , the concatenation of all linear models can be written in matrix form as in Equation 3.1.

$$\mathbf{Y} = \mathbf{XB} + \mathbf{E} \quad (3.1)$$

Where:

- $\mathbf{B}$ :  $[p+1 \times K]$  matrix of regression coefficients (with the  $+1$  referring to the intercept term);
- $\mathbf{E}$ :  $[N \times K]$  matrix of residuals.

The objective is then to find the coefficients  $\hat{\mathbf{B}}$  which minimizes the Residual Sum of Squares (RSS), which is summarized by Equation 3.3 (Friedman, Hastie, Tibshirani, et al. 2001):

$$\hat{\mathbf{B}}^{\text{OLS}} = \arg \min_{\mathbf{B}} \text{RSS}(\mathbf{B}) \quad (3.2)$$

In turn, the RSS, as the name suggests, is defined as the difference between real and predicted values, squared, which in matrix form is written as (Friedman, Hastie, Tibshirani, et al. 2001):

$$\text{RSS}(\mathbf{B}) = \text{Tr}[(\mathbf{Y} - \mathbf{XB})^T(\mathbf{Y} - \mathbf{XB})] \quad (3.3)$$

Finally, solving for  $\hat{\mathbf{B}}$  yields (Friedman, Hastie, Tibshirani, et al. 2001):

$$\hat{\mathbf{B}}^{\text{OLS}} = (\mathbf{X}^T \mathbf{X})^{-1} \mathbf{X}^T \mathbf{Y} \quad (3.4)$$

For the problem at hand, in addition to the high number of features, it is often the case that sensor data points are acquired in quick succession, which in turn leads to highly correlated features (Bastuck 2019), which can result in high variance in a least squares model (Friedman, Hastie, Tibshirani, et al. 2001). It is natural, therefore, to progress towards methods that incorporate dimensionality reduction such as Principal Components Regression (PCR) and Partial Least Squares Regression (PLSR) or shrinkage such as Ridge Regression.

### 3.3 Principal Component Analysis

One way to define Principal Components Analysis (PCA) is to view it as a orthogonal projection of the data into a principal space of lower dimension such that the variance of this projection is maximized (Bishop 2006).

Just as before, consider the collection of  $n$  observations  $\mathbf{X}$  with covariance matrix  $\Sigma$ . Additionally, consider a matrix  $\mathbf{P} = [\mathbf{p}_1, \mathbf{p}_2, \dots, \mathbf{p}_n]^\top$  where  $\mathbf{p}_i$  is a row vector of coefficients referring to the  $i$ -th linear combination (Johnson and Wichern 2013):

$$t_i = \mathbf{x}_i \mathbf{p}_i^\top \quad i = 1, 2, \dots, n \quad (3.5)$$

The variance and covariance of these new variables  $t_i$  can be written as follows:

$$\text{Var}(t_i) = \mathbf{p}_i^\top \Sigma \mathbf{p}_i \quad i = 1, 2, \dots, n \quad (3.6)$$

$$\text{Cov}(t_i, t_k) = \mathbf{p}_i^\top \Sigma \mathbf{p}_k \quad i, k = 1, 2, \dots, n \quad (3.7)$$

The first Principal Component (PC) is then the linear combination with maximum variance, i.e. the linear combinations that maximizes  $\text{Var}(t_1)$ , with the constraint that the coefficient vector  $\mathbf{p}_1$  has unit length. In summary, the first PC is computed as (Johnson and Wichern 2013):

$$\begin{aligned} t_1 &= \mathbf{x}_1 \mathbf{p}_1^\top \\ &\text{that maximizes } \text{Var}(\mathbf{x}_1 \mathbf{p}_1^\top) \\ &\text{subject to } \mathbf{p}_1^\top \mathbf{p}_1 = 1 \end{aligned} \quad (3.8)$$

The second PC, similarly to the first, is the linear combination with maximum variance, but with an added extra constraint: this new linear combination must be orthogonal to the previous one, i.e. they must be linearly independent:

$$\begin{aligned} t_2 &= \mathbf{x}_2 \mathbf{p}_2^\top \\ &\text{that maximizes } \text{Var}(\mathbf{x}_2 \mathbf{p}_2^\top) \\ &\text{subject to } \mathbf{p}_2^\top \mathbf{p}_2 = 1 \\ &\text{and } \text{Cov}(t_1, t_2) = 0 \end{aligned} \quad (3.9)$$

The k-th PC is then:

$$\begin{aligned}
 t_k &= \mathbf{x}_k \mathbf{p}_k^\top \\
 &\text{that maximizes } \text{Var}(\mathbf{x}_k \mathbf{p}_k^\top) \\
 &\text{subject to } \mathbf{p}_k^\top \mathbf{p}_k = 1 \\
 &\text{and } \text{Cov}(t_j, t_k) = 0 \quad \text{for } k > j
 \end{aligned} \tag{3.10}$$

In summary, the objective of PCA is find a matrix  $\mathbf{P}$  such that the linear transformation

$$\mathbf{T} = \mathbf{X}\mathbf{P}^\top \tag{3.11}$$

yields new variables that are uncorrelated and arranged in decreasing order of variance.

It can be shown that these desired linear combinations can be written in terms of the eigenvalues ( $\lambda$ ) and eigenvectors ( $e$ ) of  $\Sigma$ , the covariance matrix of  $\mathbf{X}$  (Johnson and Wichern 2013). The elements of eigenvectors are called loadings, while the new features  $\mathbf{T}$  are . In short, for the k-th PC:

$$\begin{aligned}
 t_k &= \mathbf{X}_k e_k^\top \\
 \text{Var}(t_k) &= e_k^\top \Sigma e_k = \lambda_k \\
 \text{Cov}(t_j, t_k) &= e_k^\top \Sigma e_j = 0 \quad \text{for } k \neq j
 \end{aligned} \tag{3.12}$$

There are several ways of computing PCs. Many of which involving finding aforementioned eigenvalues and eigenvectors. These calculations can be computationally expensive, depending on the desired number of extracted PCs (Bishop 2006). One option is the Nonlinear Iterative Partial Least Squares (NIPALS) algorithm, also called Power Method. It has two clear advantages: "it can handle missing data and computes the components sequentially" (Dunn 2021).

The NIPALS algorithm to compute the first k-th PCs,  $PC_i$ ,  $i = 1, 2, \dots, n$  is displayed below as Algorith 1 (Dunn 2021) (Ng 2013) (Wright 2017). Since it computes the loadings and scores sequentially, it is possible to stop it as early as desired. The "truncated" loadings and scores that project  $\mathbf{X}$  into the principal subspace of k PCs is defined in Equation 3.13 :

$$\mathbf{T}_{|k} = \mathbf{X}\mathbf{P}_{|k}^\top \tag{3.13}$$

**Algorithm 1:** Nonlinear Iterative Partial Least Squares (NIPALS) for PCA

---

**Result:** Matrices of loadings  $\mathbf{P}_{|k}$  and scores  $\mathbf{T}_{|k}$  of the k-th first Principal Components

```

1 Initialize  $\mathbf{T}_{|k}$  and  $\mathbf{P}_{|k}$ 
2  $i = 1$ 
3  $\mathbf{X}_1 := \mathbf{X}$ 
4 while  $i < k$  do
5   repeat
6     Choose  $\mathbf{t}_i$  as any column of  $\mathbf{X}_i$ 
7     Compute loadings  $\mathbf{p}_i = (\mathbf{t}_i^\top \mathbf{t}_i)^{-1} \mathbf{t}_i^\top \mathbf{X}_i$ 
8     Scale  $\mathbf{p}_i = \frac{\mathbf{p}_i}{\sqrt{\mathbf{p}_i^\top \mathbf{p}_i}}$ 
9     Compute scores  $\mathbf{t}_i = (\mathbf{p}_i^\top \mathbf{p}_i)^{-1} \mathbf{p}_i^\top \mathbf{X}_i$ 
10    until  $\mathbf{t}_i$  converges
11    Append  $\mathbf{t}_i$  to  $\mathbf{T}_{|k}$ 
12    Append  $\mathbf{p}_i$  to  $\mathbf{P}_{|k}$ 
13    Deflate:  $\mathbf{X}_{i+1} = \mathbf{X}_i - \mathbf{t}_i \mathbf{p}_i^\top$ 
14     $i += 1$ 
15 end
16 return  $\mathbf{T}_{|k}, \mathbf{P}_{|k}$ 
```

---

In words, the main idea of the algorithm can be summarized as choosing an arbitrary column of  $\mathbf{X}$  as the scores vector  $\mathbf{t}_i$ , shown in line 6. Next, the computation of the i-th loadings vector  $\mathbf{p}_i$  by regressing every column of  $\mathbf{X}$  via OLS onto the scores  $\mathbf{t}_i$ .  $\mathbf{p}_i$  is then scaled to have unit length in Line 8, which in turn is used to compute the i-th scores vector  $\mathbf{t}_i$  by regressing every column of  $\mathbf{X}$  via OLS onto the loadings  $\mathbf{p}_i$ , shown in Line 9. This procedure is repeated until change in  $\mathbf{t}_i$  between iterations is small enough. Once convergence is achieved, scores  $\mathbf{t}_i$  and loadings  $\mathbf{p}_i$  are stored as the i-th column of matrices  $\mathbf{T}$  and  $\mathbf{P}$  of Equation 3.11, respectively. Finally, the variability explained by  $\mathbf{t}_i$  and  $\mathbf{p}_i$  from  $\mathbf{X}$  is subtracted in a procedure called deflation.

### 3.4 Principal Component Regression

With the inner workings of PCA explained in the previous section, PCR can be simply reduced to a Least Squares regression on the first k-th PCs, i.e. performing linear regression on  $\mathbf{T}_{|k}$  instead of  $\mathbf{X}$ :

$$\mathbf{Y} = \mathbf{T}_{|k} \mathbf{B} + \mathbf{E} \quad (3.14)$$

And the regression coefficients are found analogously to Equation 3.4:

$$\hat{\mathbf{B}}^{\text{PCR}} = (\mathbf{T}_{|k}^\top \mathbf{T}_{|k})^{-1} \mathbf{T}_{|k}^\top \mathbf{Y} \quad (3.15)$$

Although useful, PCR has a potential flaw: while the new found projection of  $\mathbf{X}$  is guaranteed to best explain the variance of predictors, this cannot be said about the responses  $\mathbf{Y}$  (James, Witten, Hastie, and Tibshirani 2013). PLSR, on the other hand, solves this issue by supervising the identification of PCs (James, Witten, Hastie, and Tibshirani 2013).

### 3.5 Partial Least Squares Regression

PLSR, much like PCR, also aims to reduce dimensionality via linear combinations of the inputs. This technique, however, also takes into account the response variables  $\mathbf{Y}$ . One key advantage of PLSR is that it seeks axes with most variance (like PCR) and high correlation with response variables (Friedman, Hastie, Tibshirani, et al. 2001).

The main idea can be described as finding linear combinations for the data matrix  $\mathbf{X}$  and response matrix  $\mathbf{Y}$  as follows (Ng 2013), similarly to what was done in Section 3.3. Here, the matrices  $\mathbf{W}$  and  $\mathbf{U}$  are score matrices, i.e. the transformed PLS variables, and  $\mathbf{L}$  and  $\mathbf{Q}$  are loading matrices, i.e. the weights of this transformation (projection).

$$\mathbf{W} = \mathbf{XL}^T \quad (3.16)$$

$$\mathbf{U} = \mathbf{YQ}^T \quad (3.17)$$

Instead of simply running NIPALS on  $\mathbf{X}$  and  $\mathbf{Y}$  separately, PLSR uses information from  $\mathbf{Y}$  to decompose  $\mathbf{X}$  and vice-versa (Ng 2013). Algorithm 2 is an adaptation of Algorithm 1 to incorporate this intended behavior.

---

**Algorithm 2:** NIPALS for Partial Least Squares Regression (PLSR)

---

**Result:** Matrices of loadings  $\mathbf{L}_{|k}$ ,  $\mathbf{Q}_{|k}$  and scores  $\mathbf{W}_{|k}$ ,  $\mathbf{U}_{|k}$  of the  $k$ -th first Partial Least Squares directions

```

1 Initialize  $\mathbf{L}_{|k}$ ,  $\mathbf{Q}_{|k}$  and  $\mathbf{W}_{|k}$ ,  $\mathbf{U}_{|k}$ 
2  $i = 1$ 
3  $\mathbf{X}_1 := \mathbf{X}$ 
4  $\mathbf{Y}_1 := \mathbf{Y}$ 
5 while  $i < k$  do
6   repeat
7     Choose  $\mathbf{u}_i$  as any column of  $\mathbf{Y}_i$ 
8     Compute loadings of  $\mathbf{X}_i$  based on score of  $\mathbf{Y}_i$ :  $\ell_i = (\mathbf{u}_i^\top \mathbf{u}_i)^{-1} \mathbf{u}_i^\top \mathbf{X}_i$ 
9     Scale  $\ell_i = \frac{\ell_i}{\sqrt{\ell_i^\top \ell_i}}$ 
10    Compute score of  $\mathbf{X}_i$ :  $\mathbf{w}_i = (\ell_i^\top \ell_i)^{-1} \ell_i^\top \mathbf{X}_i$ 
11    Compute loadings of  $\mathbf{Y}_i$  based on score of  $\mathbf{X}_i$ :  $\mathbf{q}_i = (\mathbf{w}_i^\top \mathbf{w}_i)^{-1} \mathbf{w}_i^\top \mathbf{Y}_i$ 
12    Scale  $\mathbf{q}_i = \frac{\mathbf{q}_i}{\sqrt{\mathbf{q}_i^\top \mathbf{q}_i}}$ 
13    Compute score of  $\mathbf{Y}_i$ :  $\mathbf{u}_i = (\mathbf{q}_i^\top \mathbf{q}_i)^{-1} \mathbf{q}_i^\top \mathbf{Y}_i$ 
14  until  $\mathbf{u}_i$  converges
15  Append  $\mathbf{w}_i$  to  $\mathbf{W}_{|k}$ 
16  Append  $\ell_i$  to  $\mathbf{L}_{|k}$ 
17  Append  $\mathbf{u}_i$  to  $\mathbf{U}_{|k}$ 
18  Append  $\mathbf{q}_i$  to  $\mathbf{Q}_{|k}$ 
19  Deflate  $\mathbf{X}_i$ :  $\mathbf{X}_{i+1} = \mathbf{X}_i - \mathbf{w}_i \ell_i^\top$ 
20  Deflate  $\mathbf{Y}_i$ :  $\mathbf{Y}_{i+1} = \mathbf{Y}_i - \mathbf{u}_i \mathbf{q}_i^\top$ 
21   $i += 1$ 
22 end
23 return  $\mathbf{W}_{|k}$ ,  $\mathbf{L}_{|k}$ ,  $\mathbf{U}_{|k}$ ,  $\mathbf{Q}_{|k}$ 

```

---

As with Algorithm 1, Algorithm 2 can be summarized as choosing a column of  $\mathbf{Y}_i$  as the initial response score vector  $\mathbf{u}_i$ . After that, the  $i$ -th loadings vector  $\mathbf{w}_i$  of  $\mathbf{X}$  is computed in Line 8 by regressing every column of  $\mathbf{X}$  via OLS onto scores vector of  $\mathbf{Y}$ ,  $\mathbf{u}_i$ . Similarly to before, the data loadings vector  $\mathbf{w}_i$  is scaled to have unit length, which in turn is used to compute the  $i$ -th data scores vector  $\mathbf{w}_i$  by regressing every column of  $\mathbf{X}_i$  via OLS onto the column  $\ell_i$  in Line 10. Now, the  $i$ -th response loadings vector  $\mathbf{q}_i$  of  $\mathbf{Y}_i$  by regressing every column of  $\mathbf{Y}$  via OLS onto scores vector of  $\mathbf{X}$ ,  $\mathbf{w}_i$ , shown in Line 11; This loadings vector is also scaled to have unit length.

Following in Line 13, the  $i$ -th response scores vector  $\mathbf{u}_i$  is computed by regressing every column of  $\mathbf{Y}_i$  via OLS onto the column  $\mathbf{q}_i$ . This procedure is repeated until change in  $\mathbf{u}_i$  between iterations is small enough. In that case the results  $\mathbf{w}_i$  and  $\ell_i$  are stored as the  $i$ -th

column of matrices  $\mathbf{W}$  and  $\mathbf{L}$  of Equation 3.16 and  $u_i$  and  $q_i$  are stored as the  $i$ -th column of matrices  $\mathbf{U}$  and  $\mathbf{Q}$  of Equation 3.17. Finally, the variability explained by  $w_i, \ell_i$  and  $u_i, q_i$  from  $\mathbf{X}_i$  and  $\mathbf{Y}_i$ , respectively, are removed.

After finding the  $k$  partial least squares directions from Algorithm 2 above, the problem, as in Section 3.4, reduces to performing Least Squares Regression using the newfound transformations.

$$\mathbf{Y} = \mathbf{W}_{|k}\mathbf{B} + \mathbf{E} \quad (3.18)$$

Which in turn, analogously to Equations 3.4 and 3.15, yields the coefficients:

$$\hat{\mathbf{B}}^{\text{PLSR}} = (\mathbf{W}_{|k}^\top \mathbf{W}_{|k})^{-1} \mathbf{W}_{|k}^\top \mathbf{Y} \quad (3.19)$$

### 3.6 Ridge Regression

Ridge regression is also a viable alternative to reduce the problem of highly correlated features (Friedman, Hastie, Tibshirani, et al. 2001). Instead of fitting a least squares model on a subset of predictors or a transformation of them, Ridge allows the use of all features with a continuous shrinkage of its coefficients, which results in less variance (Friedman, Hastie, Tibshirani, et al. 2001).

For the multi-output case, there are two options: use the same penalization parameter  $\lambda$  for all variables  $\mathbf{Y} = [\mathbf{y}_1, \mathbf{y}_2, \dots, \mathbf{y}_K]^\top$  or apply different parameters  $\lambda = [\lambda_1, \lambda_2, \dots, \lambda_K]^\top$ . In this work, the latter is preferred over the former, as it allows a more fine tuned control of the regression models for each studied gas.

Analogous to Section 3.2, the goal is to minimize the RSS, but now with the penalization term taken into account. Equation 3.20 below shows this objective function in matrix form.

$$\text{RSS}^{\text{Ridge}}(\mathbf{B}, \lambda) = \text{Tr}[(\mathbf{Y} - \mathbf{XB})^\top (\mathbf{Y} - \mathbf{XB})] + \text{Tr}[\mathbf{B}^\top \mathbf{B} + \lambda \mathbf{I}] \quad (3.20)$$

$$\hat{\mathbf{B}}^{\text{Ridge}} = \arg \min_{\mathbf{B}} \text{RSS}^{\text{Ridge}}(\mathbf{B}) \quad (3.21)$$

The coefficients that minimize the RSS is shown in Equation ?? below.

$$\hat{\mathbf{B}}^{\text{Ridge}} = (\mathbf{X}^\top \mathbf{X} + \lambda \mathbf{I})^{-1} \mathbf{X}^\top \mathbf{Y} \quad (3.22)$$

It is important to note that the parameters  $\beta_0$  are calculated separately as the response mean  $\bar{Y}$  (Friedman, Hastie, Tibshirani, et al. 2001), i.e.:

$$\hat{\mathbf{B}}_0^{\text{Ridge}} \begin{bmatrix} \beta_{0,1} \\ \beta_{0,2} \\ \vdots \\ \beta_{0,K} \end{bmatrix} = \begin{bmatrix} \bar{y}_1 \\ \bar{y}_2 \\ \vdots \\ \bar{y}_K \end{bmatrix} = \begin{bmatrix} \frac{1}{n} \sum_{i=1}^n y_{i,1} \\ \frac{1}{n} \sum_{i=1}^n y_{i,2} \\ \vdots \\ \frac{1}{n} \sum_{i=1}^n y_{i,K} \end{bmatrix} \quad (3.23)$$

The choice of hyper-parameters  $\lambda \geq 0$  controls how much shrinkage is applied to the coefficients: larger  $\lambda$  implies more penalization to complex models. Although the coefficients are shrunk towards zero, they never reach zero, which makes Ridge regularization unsuitable for feature selection (Friedman, Hastie, Tibshirani, et al. 2001).

Finally, predictions in a ridge regression setting are computed as:

$$\hat{\mathbf{Y}}^{\text{Ridge}} = \hat{\mathbf{B}}_0^{\text{Ridge}} + \hat{\mathbf{B}}^{\text{Ridge}} \mathbf{X} \quad (3.24)$$

### 3.7 Cross Validation

There are several choices to make for the aforementioned models: How many PCs/PLS components to use? How much penalization to impose in Ridge regression?

A first answer to this would be to split the data into training and validation sets. After fitting models to the former, the latter is used to measure the prediction error via some scoring function. In that sense, it is important to distinguish test error rate from training error rate. The first, also called generalization error, is the score of the fit on an independent, previously unseen test sample. The second, on the other hand, is the average score over the training sample (Friedman, Hastie, Tibshirani, et al. 2001).

Scoring functions measure how much the data deviates from the fit and can be used as a qualitative tool for model selection and comparison. Once this is done, the choice of the model that yields minimum error is trivial. Two examples of wildly used score functions are Mean Squared Error (MSE) and Root Mean Squared Error (RMSE). For the multi-output case of  $m$  responses and  $n$  observations, they are defined respectively as :

$$\text{MSE} = \frac{1}{n} \sum_{i=1}^n \left( \sum_{j=1}^m (y_{ij} - \hat{y}_{ij}) \right)^2 \quad (3.25)$$

$$\text{RMSE} = \sqrt{\text{MSE}} \quad (3.26)$$

This approach, however, is sensitive to the choice of these sets. Additionally, reserving part of the data just for validation might be detrimental for the model fitting process, specially if the number of observations is low (James, Witten, Hastie, and Tibshirani 2013).

One tool that can help alleviating these problems is Cross Validation (CV). More specifically, K-fold CV: it involves eq  dividing the training data into  $K$  sets. For each subset, the desired model is trained using  folds and the prediction error is computed on the remaining fold (Friedman, Hastie, Tibshirani, et al. 2001). As for the final evaluation, it is performed in the held-out test set.

## 4 Methods

This chapter describes the application of theory shown in Chapter 3 applied to the pre-processed data described in Chapter 2. For further details regarding coding and implementation, the reader is referred to this work's [repository](#).

In general, the use of Scikit-Learn's `pipeline` class alongside linear models made analysis straightforward. Additionally, Scikit-Learn's `GridSearchCV` allowed for a faster evaluation of different hyperparameters such as number of components and shrinkage factor.

Throughout all methods, training, test and validation sets were split using `train_test_split`. Out of all 1500 exposures, 1200 (80%) were assigned to the training set and 300 (20%) to the validation set. The test set is embedded in the training set, as k-fold cross-validation is used. A fixed random seed of 42 was set to ensure reproducibility of results.

For reasons that will become clear in Chapter 6 - Discussions, regression analysis was done with two sets of predictor variables: first with all features, i.e. slopes and averages for each exposure, and second with only averages for unique mixtures (averaged features).

### 4.1 Ordinary Least Squares

Here treated as a baseline, OLS is fit using `LinearRegression` then evaluated using the validation set.

### 4.2 Principal Components Regression

First, a PCA was conducted via Scikit-Learn's `PCA`. With that, cumulative variance and score plots were made in an attempt of better visualizing and understanding the data.

Following that, a linear regression on the PCs was made. The number of components to use in it was found via CV with RMSE as the scoring function. After training, the model was evaluated in a held-out validation set and a actual vs. predicted plot was constructed.

### 4.3 Partial Least Squares Regression

Here, a similar procedure to Section 4.2 was conducted. Initially, PLS components were extracted via Scikit-learn's `PLSRegression` and some informative plots were made: cumulative explained variance (for both predictors  $\mathbf{X}$  and response  $\mathbf{Y}$ ), as well as score plots for the first two PLS components in an attempt to better visualize the data. The regression model was trained with the ideal number of components given by CV and later evaluated in the held-out validation set.

### 4.4 Ridge Regression

Once again, cross-validation was used to select the amount of shrinkage, i.e.  $\lambda$ . After setting  $\lambda$ , analysis proceeded as usual: fitting the regression line via `Ridge` to training data and evaluating it using the validation set.

## 5 Results

This chapter is dedicated to show the analysis' results. In favor of clarity and organization, this chapter will be divided into sections, each corresponding to a different model. The plots presented in this section were made using *ad-hoc* plotting functions.

Initially the regression analysis was done in the pre-processed data presented in Table 2.4, i.e. each observation corresponds to a gas exposure. It is important to remind the reader that in this data, each unique gas mixture was exposed (i.e. an exposure) twelve times: four frequency cycles through three experiment repetitions, yielding 1500 observations. Subsequently, the same analysis was conducted, but this time using the only average features of the mixture averages, shown in Table 2.5.

Before beginning analysis, an assessment of correlation between features is first conducted and shown in Figure 5.1.

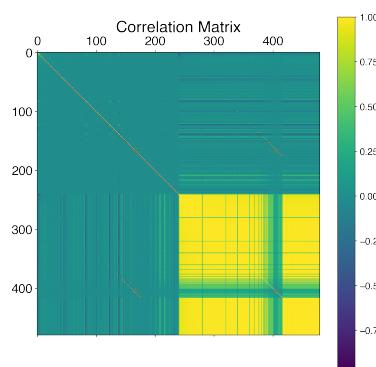

Figure 5.1: Correlation matrix of features.

In Figure 5.1, the first, mainly green, quadrant correspond to slope features, while the fourth, mainly yellow, quadrant, averages.

## 5.1 Ordinary Least Squares

As explained in Chapter 4, OLS is treated here as a baseline. The actual vs. predicted plot in Figure 5.2a shows the predictions for both data sets.

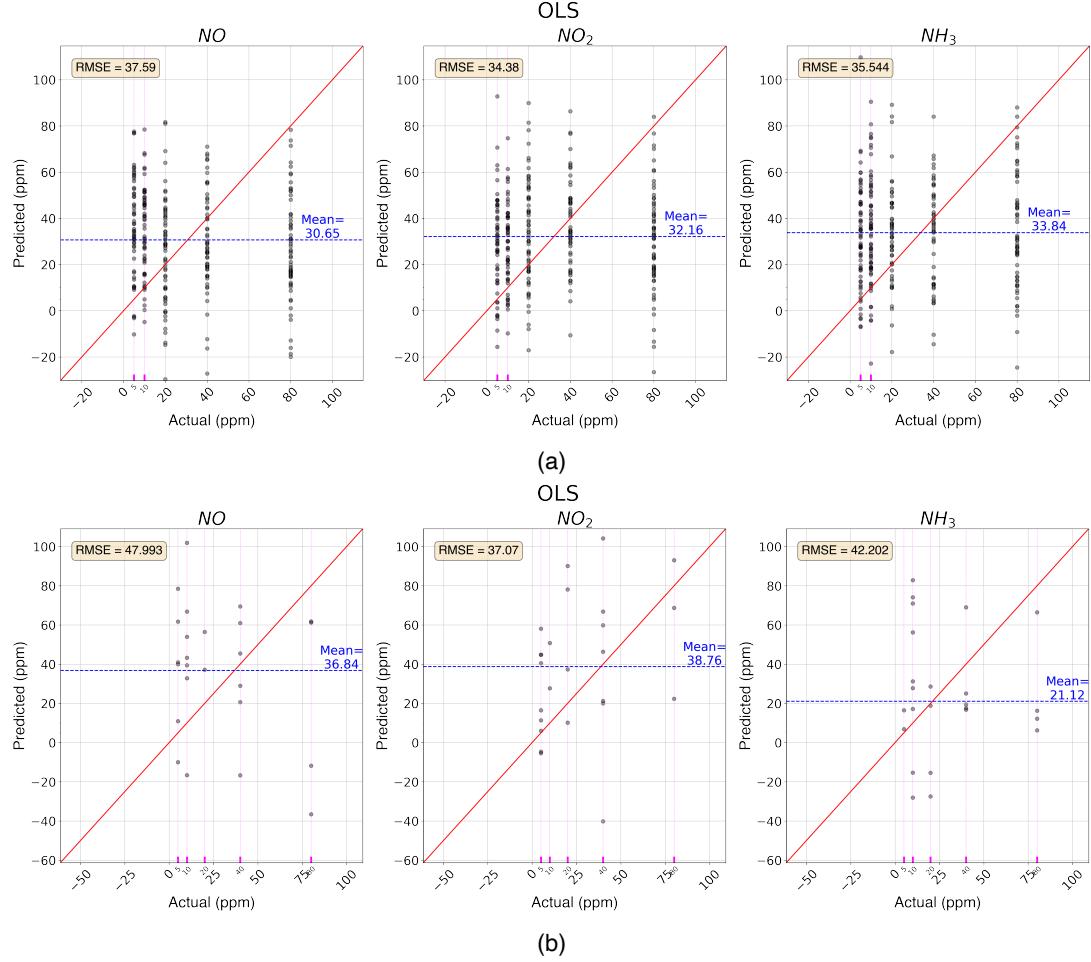

Figure 5.2: Actual vs. Predicted for (a) slopes and averages through exposures and (b) only averaged average features through mixtures.

Each subplot in Figure 5.2 corresponds to predictions of NO<sub>x</sub> and ammonia concentrations, respectively. The red diagonal line is the  $y = f(x) = x$  identity line. The blue line is the mean of predicted concentrations. The text box contains more information regarding the model fit.

## 5.2 Principal Components Regression

Following the methodology of Chapter 4, a PCA is conducted with two components in an attempt to visualize the data in a lower dimensional space in Figure ??.

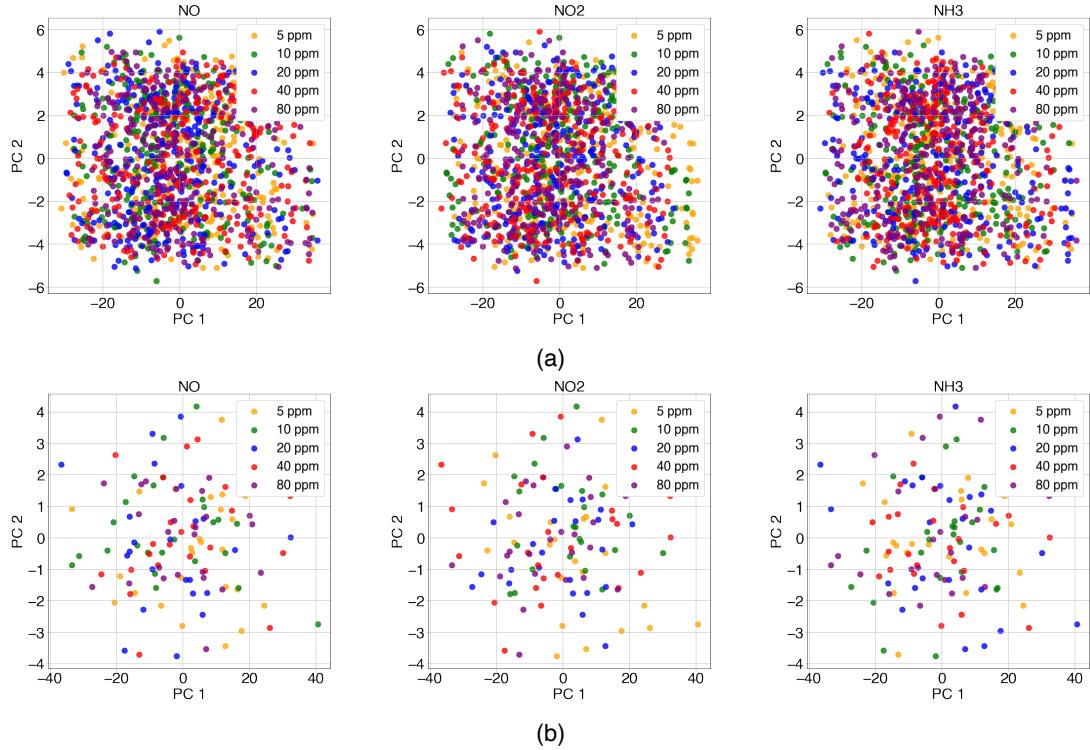

Figure 5.3: PCA for (a) slopes and averages through exposures and (b) only averaged average features through mixtures.

Furthermore, an explained variance plot is shown in Figure ???. For the first case, the first two PCs explain approximately 40% of the total variance, reaching 80% around 100 components. On the other hand, the second case achieves 90% of explained variability with two components.

After this exploration of PCA, the analysis proceeds to fit a PCR model to the data. The choice of number of PCs was made via cross-validation using RMSE as the loss function, as can be seen in Figure 5.5. Choosing only one components yields the minimum loss for both cases, around 27.

After choosing the number of components, the regression was fit to the training data and used to predict unseen validation data. The results are shown in Figure 5.6.

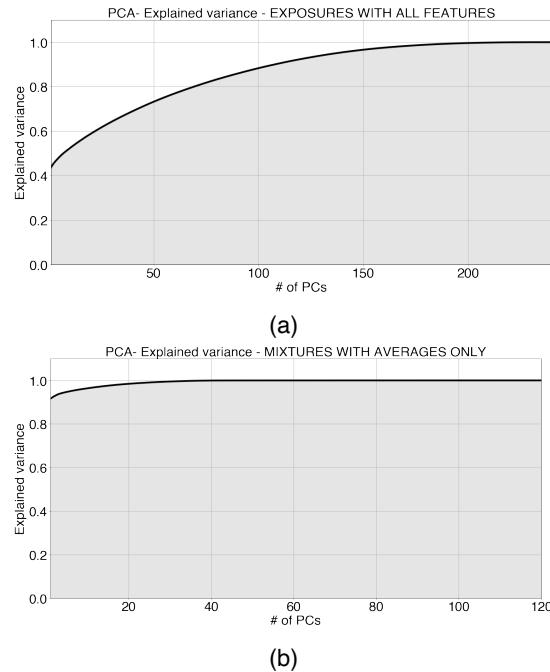

Figure 5.4: Explained variance of PC for (a) slopes and averages through exposures and (b) only averaged average features through mixtures.

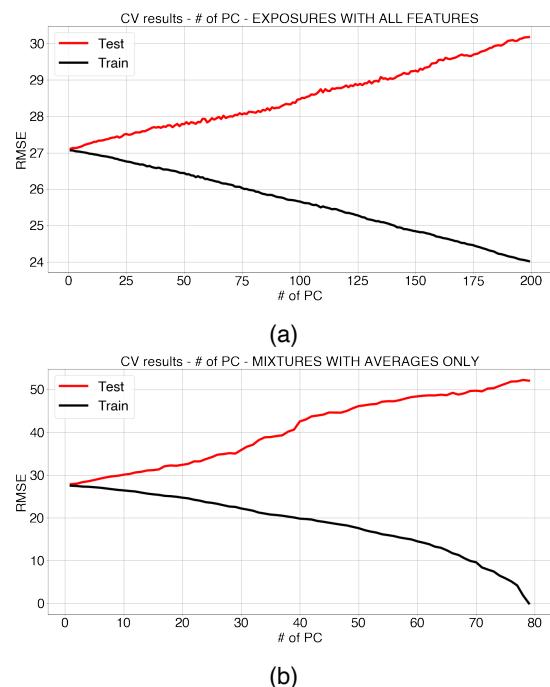

Figure 5.5: Cross-validation results for (a) slopes and averages through exposures and (b) only averaged average features through mixtures.

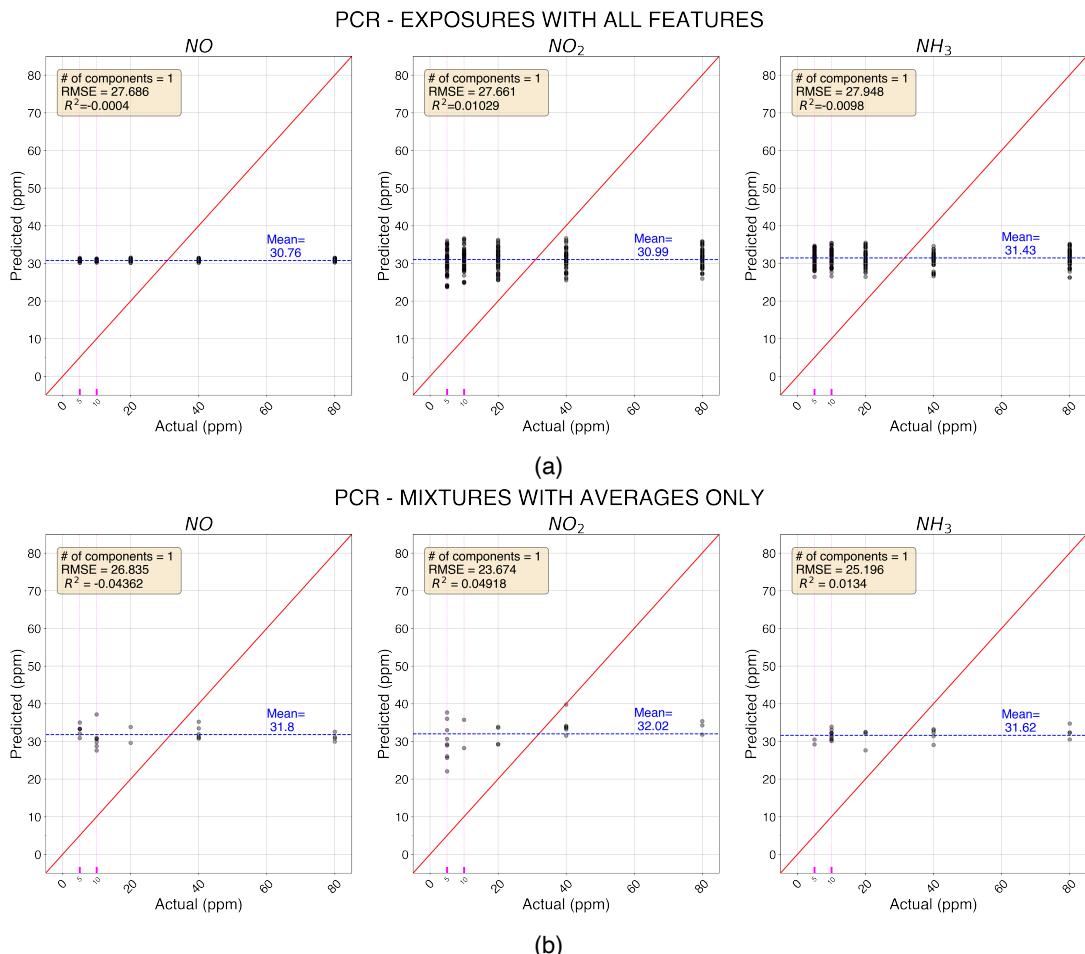

Figure 5.6: PCR for (a) slopes and averages through exposures and (b) only averaged average features through mixtures.

### 5.3 Partial Least Squares Regression

Following the proposed model progression, the analysis proceeds to fit the PLSR model. A similar pipeline to Section 5.2 was used. First, in Figure 5.7, the choice of only two PLS components allowed visualization of data in a two dimensional plot. Moreover, total explained variance is shown in Figure 5.8. Once again, cross-validation using RMSE yields a single component as the best choice, which is then used to fit and predict gas concentrations in Figure 5.10.

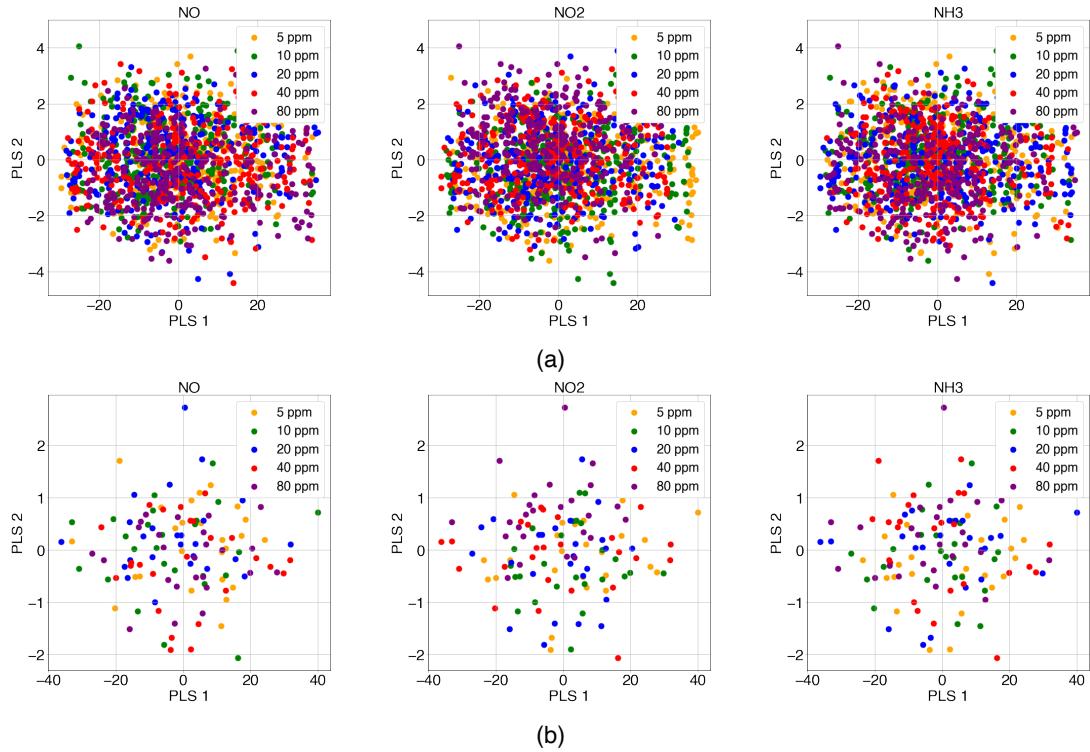

Figure 5.7: PLS scores for (a) slopes and averages through exposures and (b) only averaged average features through mixtures.

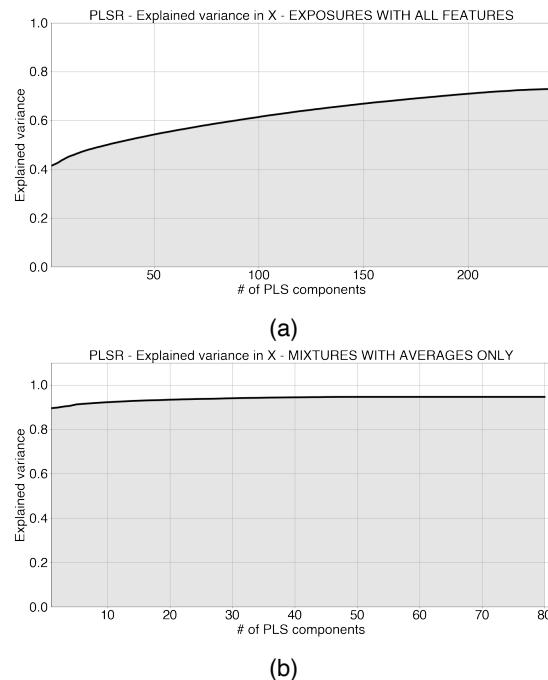

Figure 5.8: Explained variance of PLS components for (a) slopes and averages through exposures and (b) only averaged average features through mixtures.

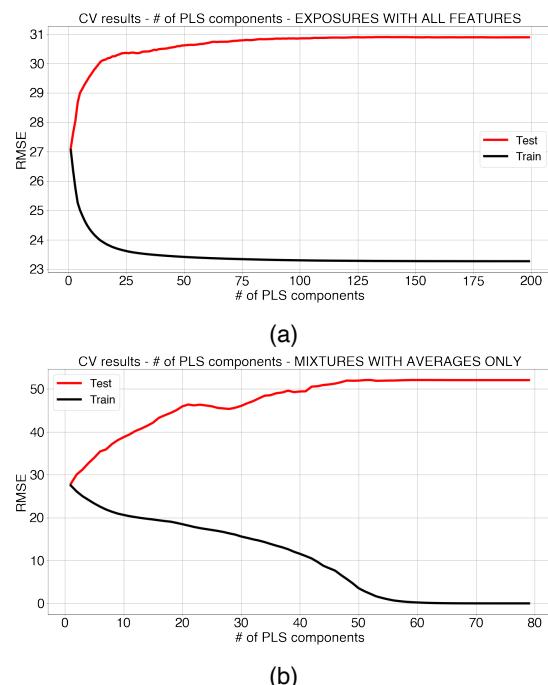

Figure 5.9: Cross-validation results for (a) slopes and averages through exposures and (b) only averaged average features through mixtures.

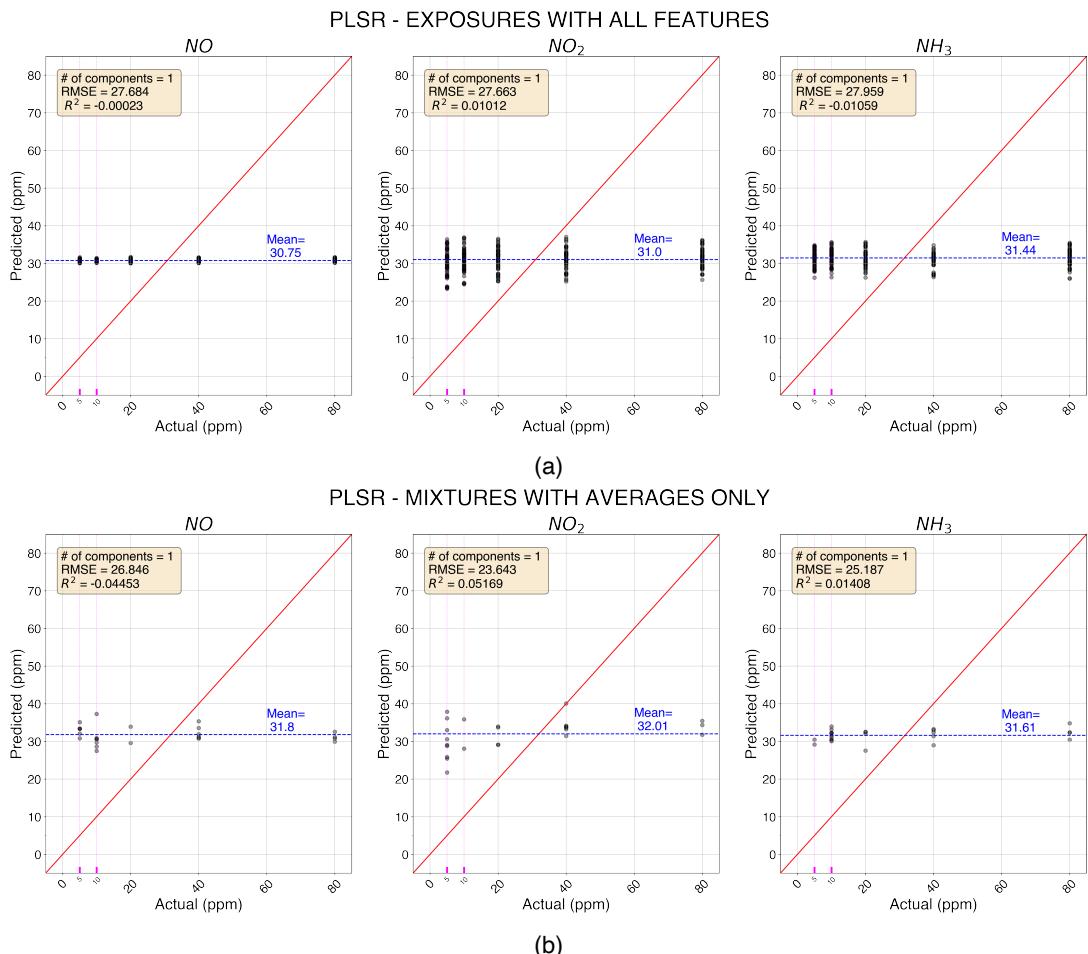

Figure 5.10: PLSR for (a) slopes and averages through exposures and (b) only averaged average features through mixtures.

## 5.4 Ridge Regression

For Ridge regression, the regularization term  $\lambda$  was chosen via cross-validation, as shown in Figure 5.11. Additionally, the shrinkage of coefficients can be seen in Figure 5.12. As expected, the coefficients shrink asymptotically towards zero.

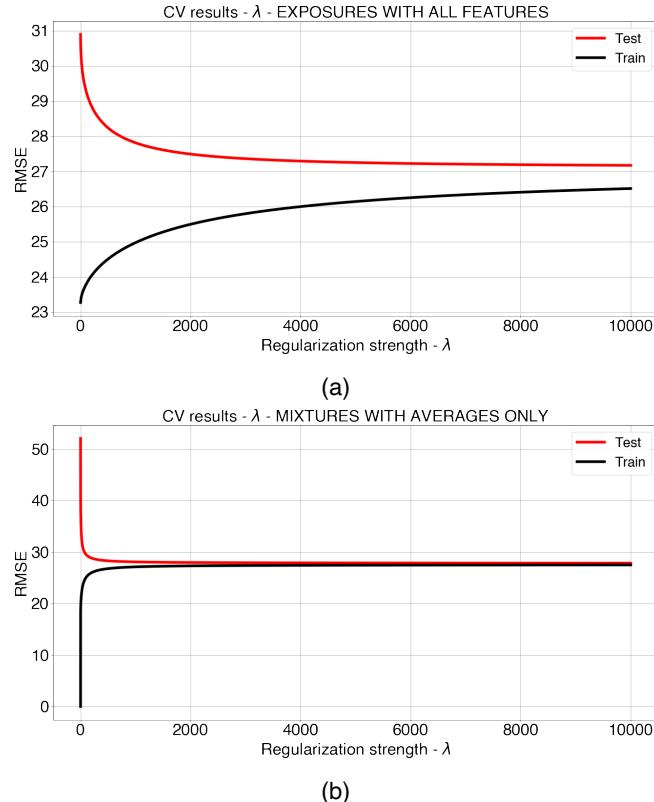

Figure 5.11: Cross-validation results for (a) slopes and averages through exposures and (b) only averaged average features through mixtures.

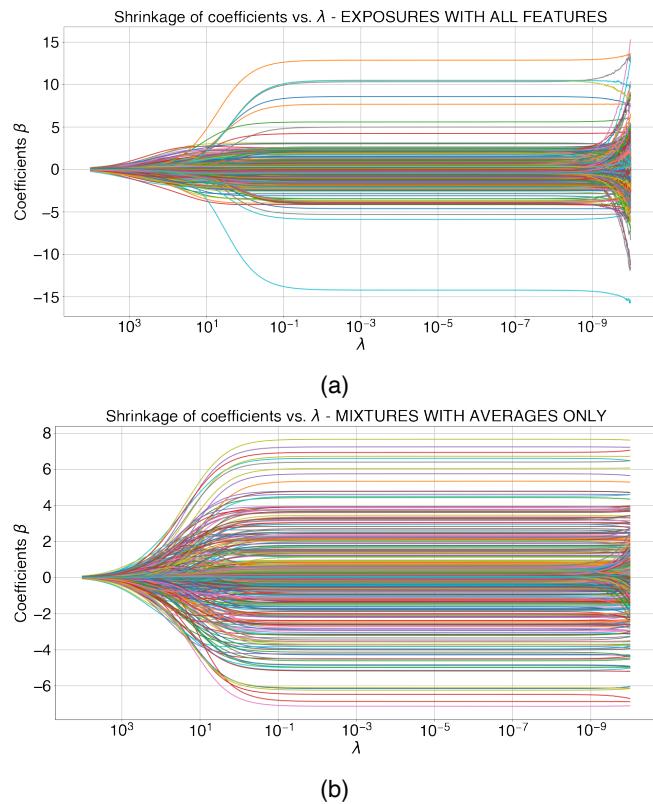

Figure 5.12: Coefficient shrinkage given  $\lambda$  (a) slopes and averages through exposures and (b) only averaged average features through mixtures. Each line corresponds to a coefficient/feature

Finally, after the choice of  $\lambda$ , the actual vs. predicted plot is presented if Figure 5.13.

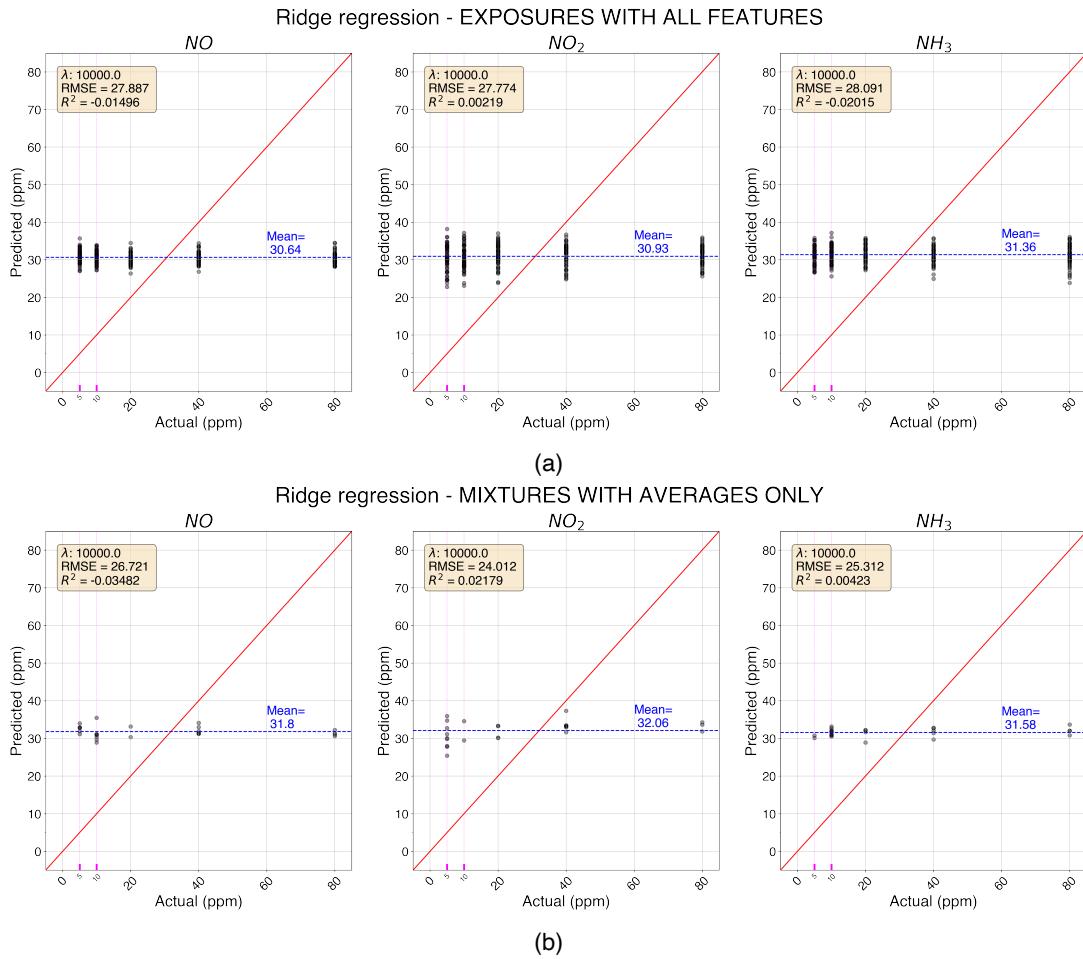

Figure 5.13: Ridge regression predictions for (a) slopes and averages through exposures and (b) only averaged average features through mixtures.

## 6 Discussion

This chapter is dedicated to explain the results obtained in the previous sections and relating them to statistical theory. The main objective here is to explain why the results are not satisfactory for gas concentration predictions.

### 6.1 Results

From the results shown in Chapter 5, it is clear that all models fail in predicting gas concentrations. As a first visual assessment, it can be seen from Figures 2.8a and 2.8b that there seems to be no clear order of response variables, i.e. simultaneous gas concentrations.

Slope features, for example, are approximately zero throughout the cycle, with the exception of some particular measurements as seen in Figure 2.8a. Even then, visual inspection indicates that this feature is not informative of gas concentrations. For this reason, the second part of the analysis was done without these features.

Average features, on the other hand, seem to have some separation and indicate that gas concentrations might be explained by it. Nonetheless, it is not possible to order in any clear way. For example, mixtures with high concentrations of NO have average features that vary wildly, and it does not seem to follow any particular linear order of ammonia or  $\text{NO}_x$  concentration levels. Further attempts at ordering the data can be found in Appendix B.

Ordinary Least Squares was expected to perform poorly, due to the high correlation of average features evidenced in Figure 5.1. Indeed, the results fail to predict gas concentrations at a reasonable level as seen on Figure 5.2a. Looking at the actual vs. predicted plot, it can be seen that the predictions are centered at the mean of concentrations (31 ppm) and have high variance, indicated by the wide range of prediction in all concentration levels.

PCA with two components confirmed previous suspicions: there is no clear separation of gas concentrations for any of the gasses. Although Figure 5.4 shows that 80% of the variance can be explained by approximately 80 components, cross-validation indicate that only one PC yields minimal error before it starts to over fit the training data. Predictions in Figure 5.6 are poor, but have significantly less variance around the concentration mean than OLS. This is expected from this method, as the extraction of PCs is tightly related to the explained variability of the predictors, selecting linear combinations ordered by "importance" to the result.

PLSR, a method that has been shown to work in this type of problem, also performed poorly. Once again, there is not clear separation of concentration levels as shown in Figure 5.7, and CV shows that only one component, again, yields minimal RMSE. Prediction results in Figure 5.10 is very similar to predictions from PCR: centered around the mean with lower variance than OLS.

The final proposed model, Ridge regression, also fails completely in prediction, but brings meaningful insights for analysis. The CV plot for the shrinkage factor  $\lambda$  shows a curious behavior: with low values of  $\lambda$ , regression seems to fit training data well, with a relatively low RMSE of approximately 23. However, this is not the case for validation set. From the plot, extremely high values of regularization yields lowest RMSE in the test set, around 27. From Equations 3.22, 3.23 and 3.24, it can be seen that for high  $\lambda$ , the regression converges to a model that only predicts the mean (in this case, 31 ppm). A virtually "infinite" regularization would achieve best prediction in this case.

## 6.2 Method

In hindsight, the results indicate that the selection of linear models was ill-advised. Although PLSR seems to work well for problems using TCO, this is not the case for frequency modulation with  $\text{NO}_x$  and ammonia. For future work, non-parametric models are recommended. Perhaps their high flexibility and lack of assumptions about data could be of aid in achieving better prediction metrics.

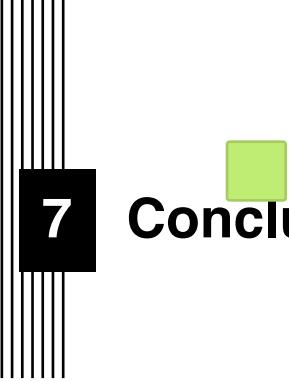

Additionally, the frequency cycle itself could be changed. Most notably, instead of a square wave signal, a triangular wave could be more desired, as it would imply in less "stable" sections of the sensor response, possibly yielding more meaningful features, specially slopes.

## 6.3 The work in a wider context

From a statisticians point of view, it is always a misfortune when analysis' results are not "good" in the sense of high accuracy or low prediction error. These arbitrarily "bad" results, however, bring more insight to the problem, and knowing what does not work might be as valuable as knowing what works.

The quantification of  $\text{NO}_x$  and Ammonia, as shown in Chapter 1, is of paramount importance in the current world, where combustion processes are still commonplace. Although

the advent of ever-improving electric vehicles is a silver lining regarding gas emissions and combustion processes, some industrial processes cannot avoid it.

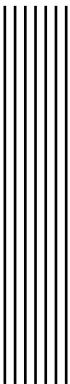

## 7

## Conclusion

Given previous discussions and analysis, the answer to the research question "Can frequency modulation be used to simultaneously quantify NO<sub>x</sub> and Ammonia concentrations?" seems to be: "perhaps not". Although poor predictions, the methods used here are far from exhausting the several other, possibly more flexible, models in the statisticians toolbox. Moreover, experiments using different frequency modulations (e.g. triangular waves instead of square) and/or different sensor calibrations and/or different temperatures could be further investigated in order to answer this question conclusively.

As for the second question "Which method yields best predictions of gas concentrations?", the correct answer would be "none". Nonetheless, out of all proposed methods, PLSR has best relative performance in terms of RMSE.

The author finds comfort in perhaps pointing future work towards better methods and possibly better quantification of these gases in hopes of addressing the problem more efficiently than current practices. In this sense, this thesis work is considered successful.

## B

## Other data plots

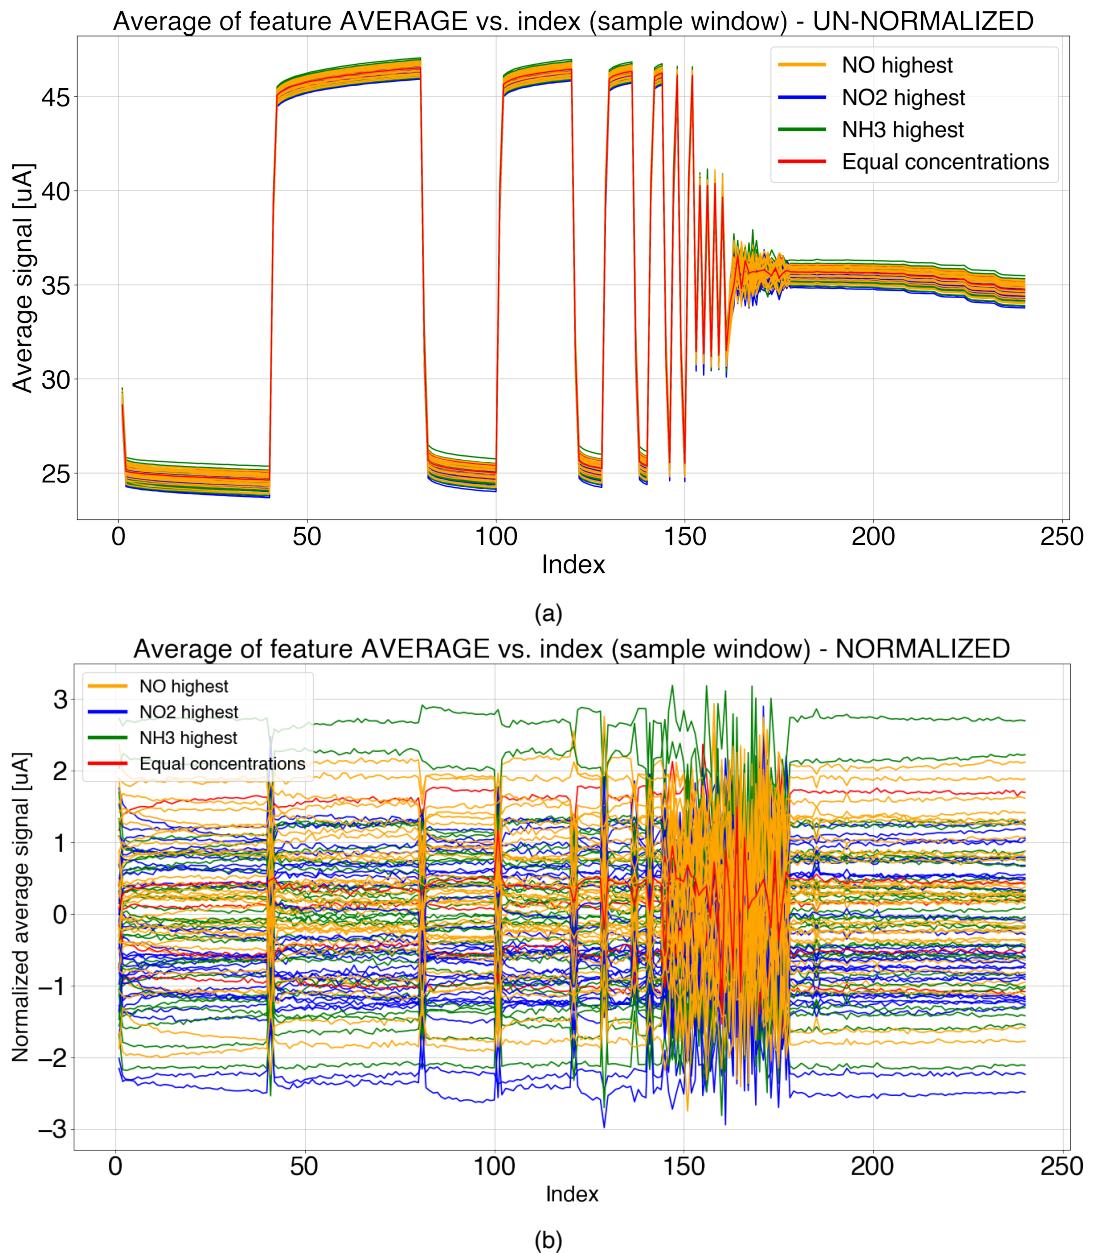

Figure B.1: Averaged sensor average divided by predominant gas. Each line corresponds to an unique mixture.

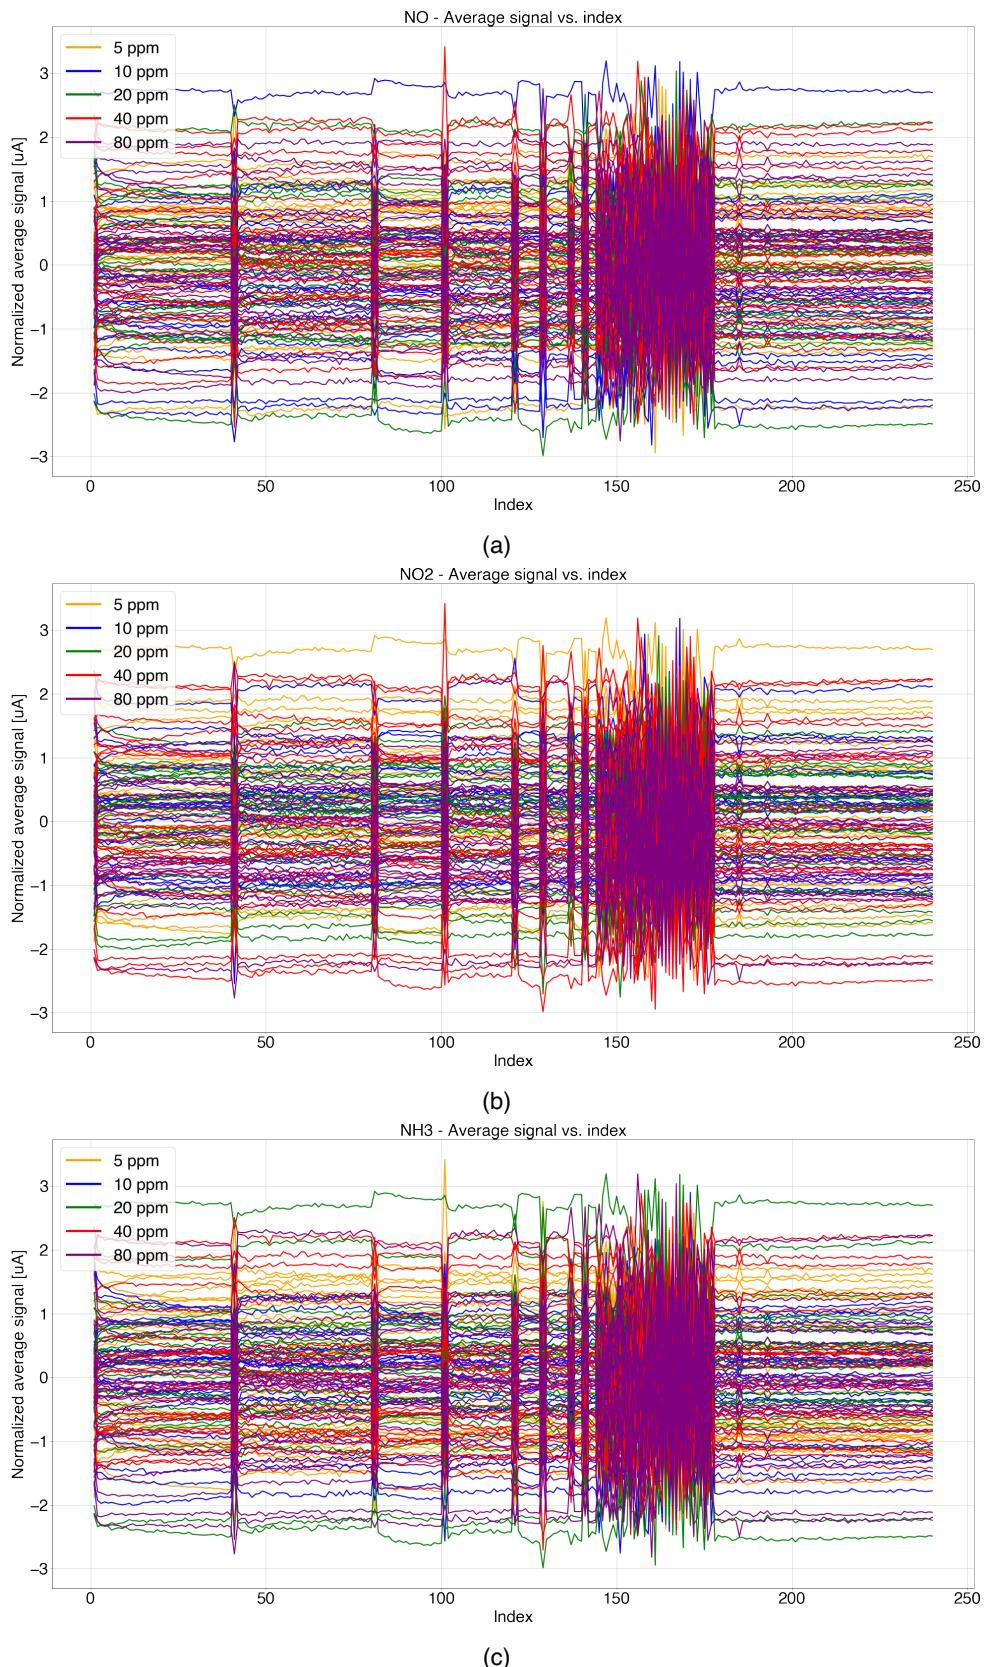

Figure B.2: Normalized sensor averaged per gas. Each line corresponds to an unique mixture. The levels are the concentrations of individual components of the mixture: (a) NO (b) NO<sub>2</sub>, and (c) NH<sub>3</sub>
